

# Covid-19 report: What does herd immunity mean for South Africa?

By [GroundUp](#) and [Spotlight staff](#)

5 Jun 2020

The latest quality Covid-19 science on schools and children, evidence that physical distancing, masks and eye protection work, herd immunity and what it means for South Africa, natural deaths in Cape Town are higher than normal, interesting data from the National Institute for Contagious Diseases (NICD), clinical trial finds no prevention benefit for hydroxychloroquine and people who undergo surgery and get the virus have a high death rate.

## School and Covid-19

Children are less likely to get ill from Covid-19 than adults. This [review](#) of 45 scientific papers from January to March found that children accounted for 1 to 5% of diagnosed cases. The largest dataset they looked at, a Chinese one, considered anyone up to 19 years old a child.

Children usually had milder disease than adults and deaths were rare. For example in Italy, at the time of the study, no one under the age of 30 had died of Covid-19.

The authors write: "Diagnostic findings have been similar to adults, with fever and respiratory symptoms being prevalent,

but fewer children seem to have developed severe pneumonia.”

An [editorial in the same journal](#) says: “[E]ven though children tend to have mild forms of Covid-19, that does not mean that we should ignore those who have the disease. We still need to take measures to prevent them becoming infected if we are to mitigate the pandemic.”

In South Africa, as of Wednesday, five of the 792 [recorded deaths](#) are in people younger than 20, less than 1%.

There is little reliable research on how infectious children are in a school environment. This [article](#) in The Conversation examines the limited data from schools in several countries. It has many useful links to primary sources. It concludes that for England, a “progressive return of children back to school, supported by adequate preventive measures and an effective test, track and isolate strategy” is advisable. How applicable to South Africa this is isn’t clear.

The World Health Organisation has published [key messages](#) for controlling Covid-19 in schools. Parents, teachers and learners should read it.

South African schools reopen as the epidemic escalates in some areas. Many children have to use cramped public transport like minibus taxis, and classrooms are often overcrowded. A large number of older people [live](#) in the houses of school-going children.

About a third of our teachers are [over the age of 50](#); while this isn’t high by world standards, a quarter of the Covid-19 deaths in this country so far have been in people aged 50 to 60. This is a much younger age distribution of Covid-19 deaths than in Europe, although we do have a much younger population, so a younger distribution is expected.

## Prevention: What works?

The Lancet has published a [review](#) of prevention studies to see how effective different interventions are. The researchers found evidence that keeping one metre distance between people was protective and the effect increased as distance lengthened. Face masks can “result in a large reduction in risk of infection”. N95 or surgical masks are better than cloth masks. Wearing eye protection (goggles or face shields) is also useful.

But a key message is that the evidence supporting all of these interventions needs to be strengthened. “Robust randomised trials are needed to better inform the evidence for these interventions, but this systematic appraisal of currently best available evidence might inform interim guidance,” the authors write.

## What does herd immunity mean?

There has been much discussion since the pandemic started about herd immunity.

In a model of an epidemic, the herd immunity threshold is crossed when enough people are immune that the number of new cases begins to decline. At this point each infected person infects on average less than one other person. (The technical explanation is that it’s [where R goes below 1](#).)

Why does it happen? Let’s say each infected person on average infects two other people, at the beginning of the epidemic. At some point in the epidemic, when 50% of people are infected in this case, then on average, one of those two people who would have been infected has already been infected, and so (we hope) cannot be infected again. Hence, on average, each infected person now only infects one other person. As the infection mark passes 50%, this dips to below one person on average, ultimately reaching zero.

But the epidemic does not end at this herd immunity threshold — 50% in our example. It may only disappear when 80% of people are infected. It depends on how many people were still infected when the herd immunity threshold was reached. If 8 million people in South Africa are still infectious when herd immunity is reached, the epidemic is very far from over. But if

800 are infectious, the epidemic is almost as good as over.

In the real world, herd immunity is a much more complex and fluid thing:

- It differs from place to place. A crowded informal settlement like Nyanga in Cape Town will have a much higher herd immunity threshold than an upmarket less densely populated suburb like Houghton in Johannesburg.
- Even for a particular suburb, the herd immunity threshold is not set in stone. If people wear masks, keep their distance from each other at taxi ranks and shopping malls, and attend large gatherings less often, then infectiousness, and consequently the herd immunity threshold, will decrease.
- Sweden has an average household size of 2.2. South Africa's is about 3.3. For this and other reasons (e.g. Swedes might be more adherent to social distancing) we can expect Sweden to have a lower overall herd immunity threshold than South Africa.
- If we all lived our lives like we did before 15 March, the herd immunity threshold in each of our communities would have been much higher than it will be now because many of us leave the house less often, wear masks, attend fewer gatherings, and keep our distance from people. In other words, our behaviour changes since 15 March will almost certainly massively reduce the ultimate number of infections and deaths.
- Crucially, "flattening the curve" does much more than delay the same ultimate number of infections; it reduces the ultimate number of infections.

## Natural deaths in Cape Town now above normal

There has been a spike in natural deaths in Cape Town (natural deaths are those not caused by violence, accidents and suicide). In the latest Medical Research Council (MRC) [report](#) natural deaths in Cape Town were 25% above what would be expected for the week ending 26 May, and 10% above the upper bound of what's expected. (This is shown on a graph so we don't have exact numbers, but it's just over 700 actual deaths versus under 600 expected deaths.)

Countrywide the number of deaths is still lower than expected because of fewer homicides and vehicle collisions during lockdown.

The MRC tallies death data weekly from the National Population Register. Unregistered deaths as well as registered deaths of people without an ID number are not recorded. The register is estimated to be about 86% complete. Currently deaths under age 1 are also not included in the MRC report.

## A wealth of information from the NICD

The NICD continues to publish many useful reports. Their [weekly testing report](#) (up till 23 May) shows that the proportion of people testing positive in the most recent week is 7.2% - with the Western Cape and Eastern Cape at 17.5% and 8.8% respectively. Earlier in the epidemic the national proportion testing positive hovered around the 3% mark.

The NICD also reports that the mean test turnaround time in the public sector had risen from 2.5 days to 8 days over the preceding month due to laboratory backlogs. The latest [epidemiological report](#) shows that the crude case-fatality-ratio in South Africa is now about 2%.

The NICD also publishes [hospital admission reports](#). The [latest one reports](#) that there have been 3,411 Covid-19 admissions in 207 facilities across the country (this includes both public and private sector). The median age of admission was 49 years old.

Interestingly, more than half the admissions have been women. In South Africa, in contrast to the rest of the world, there are almost an equal number of female and male deaths (slightly more men). By contrast in New York, 62% of deaths are men. Could this be related to the fact that there is a very high obesity prevalence among South African women? (Obesity is one of the main factors associated with Covid-19 death.)

## Topsy-turvy week for hydroxychloroquine

It has been a topsy-turvy week for the drug hydroxychloroquine. The Lancet issued an expression of concern “to alert readers that serious scientific questions” have been raised about a study on hydroxychloroquine published in the journal last week. The study was widely reported on and featured in Covid-19 Report last week. According to the Lancet an independent audit of the data in the study has been commissioned. The Guardian has [investigated](#) and [analysed](#) what happened.

Then on Wednesday the New England Journal of Medicine (NEJM) [reported](#) the results of a randomised double-blind clinical trial of hydroxychloroquine to see if it prevented infections in people exposed to Covid-19. 49 of 414 people receiving hydroxychloroquine versus 58 of 407 people receiving placebo developed Covid-19. This is not a statistically meaningful difference, meaning the drug wasn't effective.

Participants on the hydroxychloroquine arm reported more side-effects, but there were no severe adverse events.

Many of the papers we link to need not be read beyond the abstract, but randomised clinical trials are the gold standard of medical research, and this paper, along with the NEJM [editorial](#), is worth reading in full, including for its limitations.

This isn't entirely the end of the road for hydroxychloroquine, a drug that has become so heavily and unfortunately politicised. But even if some use for it is found against Covid-19 it is likely to be quite limited.

## Surgery and death during the Covid-19 pandemic

You may have been wondering why hospitals are trying to delay elective (non-emergency) surgery as much as possible. A [study](#) in The Lancet shows that people having surgery who develop Covid-19 have a very high death rate.

Of 1,128 patients in 235 hospitals in 24 countries who had confirmed SARS-CoV-2 infection from 1 January to 31 March, 268 (24%) had died within 30 days. Most had emergency surgery.

The authors conclude: “Thresholds for surgery during the Covid-19 pandemic should be higher than during normal practice, particularly in men aged 70 years and older. Consideration should be given for postponing non-urgent procedures and promoting non-operative treatment to delay or avoid the need for surgery.”
